Abstract

Traditionally, both researchers and practitioners rely on standard Erlang queueing models to analyze call center operations. In those models, service times are assumed to be independent and identically distributed exponential random variables with a constant mean. Going beyond such unrealistic assumptions has strong implications, as is evidenced by theoretical advances in the recent literature. However, there is very little empirical research, analyzing the statistical properties of service times in practice, to support that body of theoretical work. In this paper, we carry out a large-scale data-based investigation of service times in a call center with many heterogeneous agents and multiple call types. We observe that, for a given call type: (a) the service-time distribution depends strongly on the individual agent, (b) that it changes with time, and (c) that average service times are correlated across successive days or weeks. We develop stochastic models that account for these facts. In our proposed models, the service-time distribution is assumed to be lognormal with a mean that obeys a linear mixed-effects model with a weekly Gaussian random effect, and these successive weekly effects obey an autoregressive process of order one. We compare our models to simpler ones, e.g., where the mean service time depends only on the agent and call type, or only on the call type, and we find that our proposed models have a better goodness-of-fit, both in-sample and out-of-sample. We also perform simulation experiments to show that the choice of model can have a significant impact on the estimates of common measures of quality of service in the call center. Our study provides empirical support to the theoretical

research that goes beyond standard modelling assumptions in service systems.

In this online supplement, we present further supporting material. In §1, we describe several alternative service-time models which we considered but which did not lead to any improvement in the out-of-sample prediction of mean service times. In §2, we present a detailed description of our estimation/ prediction procedure for corresponding to §5 of the paper. In §3, we present additional details for the simulation experiments. In §4, we present additional tables and plots.

1. Alternative Models

In addition to Models 1, 2, and 3, and the two benchmark models, we experimented with several other models and compared their performances via a detailed statistical analysis of the data. In what follows, we briefly describe those models and explain why we do not report them separately in the main paper.

Number of call types handled. As illustrated in Figure 9 of the paper, the number of different call types handled by an agent might influence his/her average service time. For example, Figure 9 suggests that the agent slows down as he handles more call types, e.g., she/he may be getting tired and therefore less efficient. We observed a similar pattern for a few other agents in our data set as well. Based on this observation, we considered a fixed-effects model, for the mean service time of an agent/skill combination, where we included the number of different call types handled concurrently by the agent as a covariate.

Specifically, for each agent, we calculated the number of call types that this agent handles on each day. Then, for each agent/skill pair, we considered two different models: (1) we let the number of call types be a categorical variable in the model; and (2) we let the number of call types be a numerical variable in the model (i.e., we add a slope times the number of call types handled on each day, and an intercept). We did not include a linear trend in either models. We found that both models perform worse, in terms of predictive accuracy, than the rest of the models considered in this paper, so we did not consider them here.

Jointly modelling different agents. There may be some unobserved (to us) reason which affects the performance of all agents handling a given call type in a similar way, on a given day or week, by making their service times either longer or shorter. Motivated by this, we considered a model where we jointly modeled the service times of different agents who handle the same call type. Specifically, we considered a mixed-effects model for the mean service time (just as in Models 2 and 3) where we merged alternative agents together and had the same weekly random effect common to all agents. The intercepts and the slopes of the linear trends in the model were specific to each agent considered.

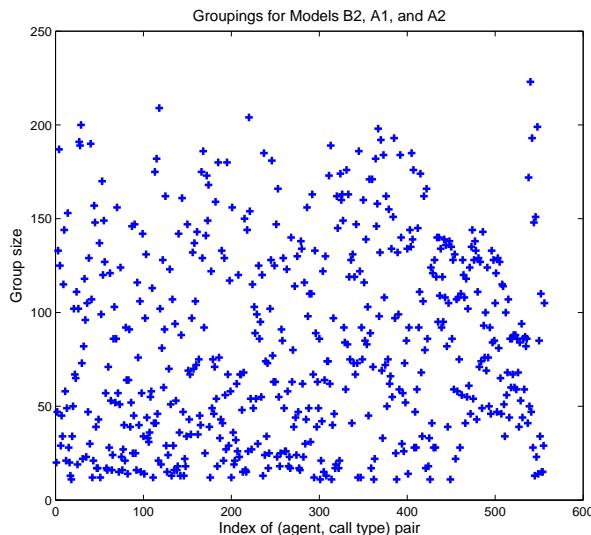

Figure 1: Groupings for Models $B2$, $A1$ and $A2$.

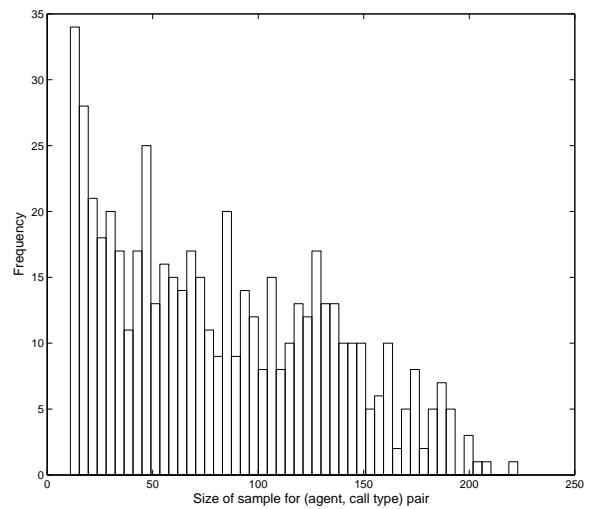

Figure 2: Histogram for Models $B2$, $A1$ and $A2$.

We found that such a model usually performs worse than Model 2 and Model 3. Moreover, due to computational restrictions, we were only able to jointly model relatively few agents (typically about 10 agents) at a time, which is not representative of the entire agent population. Therefore, we do not consider this model separately in this paper.

Multiplicative models. Since it may be natural to have multiplicative random factors affecting the mean, we considered multiplicative models in addition to the additive ones of this paper. In particular, we modelled the logarithm of the mean service time, which amounts to considering a multiplicative model for the mean. We found that modelling the mean was generally better than modelling its logarithm. For example, we tested whether the logarithm of the mean was well modelled by a Gaussian process, and found that this was generally not the case. Also, we found that such models (of the logarithm) did not generally lead to improvement in predictive accuracy over models of the mean.

2. Prediction of Average Service Times

We now present detailed numerical results describing the accuracy of out-of-sample predictions for each agent in our cohort C. We reported our results for the in-sample goodness-of-fit of our models in §4 of the paper. Here, in Figures 1-6, we plot scatter plots and histograms for the sample sizes for the alternative groupings of the overall dataset which were employed to formulate the different service-time models. It is important to do so since several ways of grouping data correspond to different size of the sample employed to estimate appropriate model statistics, and the sample size is a primary determinant of the estimation accuracy.

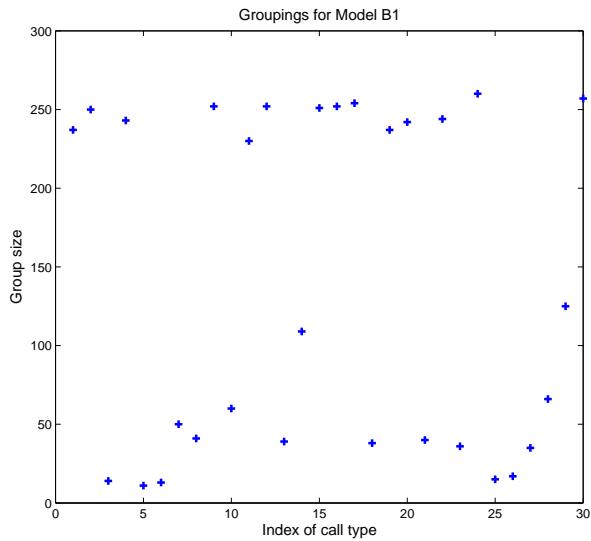

Figure 3: Groupings for Models *B1*.

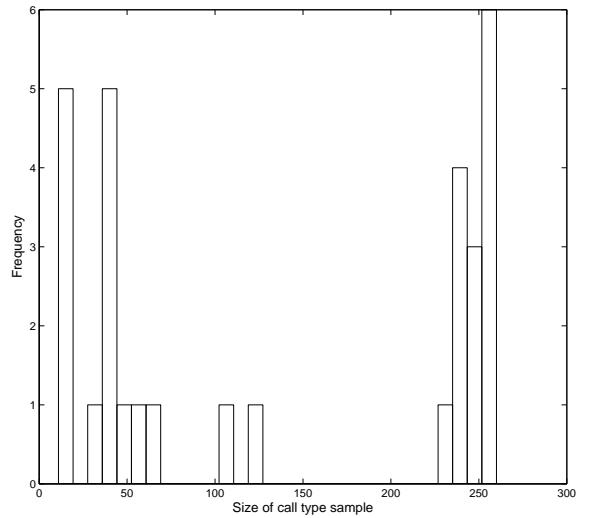

Figure 4: Histogram for Model *B1*.

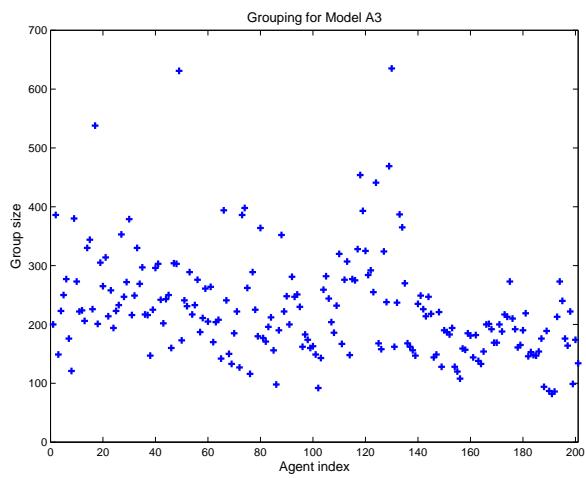

Figure 5: Groupings for Models *A3*.

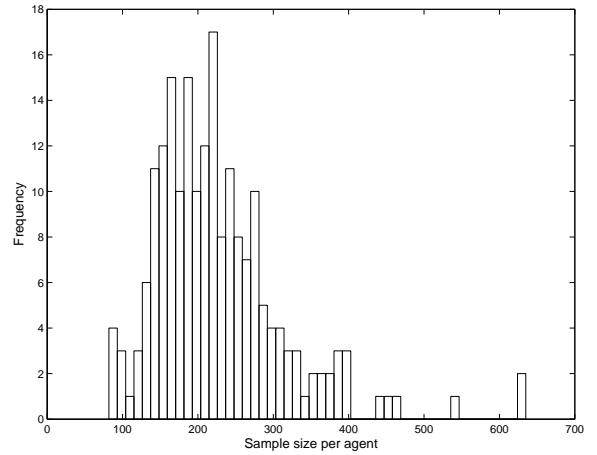

Figure 6: Histogram for Model *A3*.

The results that we present here were aggregated (averaged across all agents) and described in Table 6 of the main paper. In Tables 3, 4, and 5, we report the MAPE and RMSE for all agents in our cohort, with forecasting lead times of 1 day, 1 week, and 2 weeks, respectively. The results in Tables 3, 4, and 5 are averaged across all skills handled by the same agent. In each table, an agent may handle several call types, ranging from a minimum of 1 to a maximum of 8 call types.

For each agent, we report the total number of predictions made (this is the second column in Tables 3, 4, and 5), by combining all predictions made for that agent including all different call types that s/he handles. Since different agents handle different call types on different days, which need not be consecutive, we needed to think of systematic ways of determining the number of predictions to be made per agent. This issue was further complicated by the fact that our different models correspond to different ways of modelling the data. For example, in Model B2, Model 1, and Model 2, each (agent, call type) pair is modelled separately. In Model 3, each agent is modelled separately. And, in Model B1, each call type is modelled separately. So, the learning samples used for each prediction are different depending on the model. We first did predictions under each model separately, and then compared the predictions made under all models for the same days, in order to be consistent. We provide additional explanation below.

For Model B1, Model 1, and Model 2, we determined the number of predictions per (agent, call type) pair as follows. We focused on the subset of our data corresponding to a particular (agent, call type) pair, and divided this sample in half. We then made out-of-sample predictions for half of the data subset. For example, if we have a sample of 100 days where a given agent handles a particular call type, then we did out-of-sample predictions for the final 50 days. We did this for all (agent, call type) pairs. To further illustrate: Suppose that agent X handles only two call types A and B. In the data, suppose that agent X handles type A for 50 days, and handles type B for 100 days. In this case, we made 25 out-of-sample predictions for the pair (X, A) and 50 out-of-sample predictions for the pair (X, B). Then, the total number of predictions that we made for agent X would be: $25+50 = 75$.

For Model 3, we focused on subsets of the data corresponding to particular agents. Thus, in order to make out-of-sample predictions under this model, we focused on each agent and divided the total data corresponding to that agent in half (we indexed the data by the day, and truncated at the median of the sample of days). Then, we made out-of-sample predictions for the second half the data, using the first half as the learning set (and rolling the learning horizon forward, while preserving the forecasting lead time). For Model B1, we focused on subsets of the data that correspond to particular call types. Thus, in order to make out-of-sample predictions for this model, we focused on each call type and divided the total data

corresponding to that call type in half. Then, we made predictions for the second half the data as above. In order to make meaningful comparisons between the different models, we need to focus on days for which we have predictions under all models. We computed the number of such days per agent, and included those numbers in the tables below: These are the total number of predictions made per agent, which correspond to column 2 in the tables. The total number of predictions made across all agents is equal to 18,586 predictions.

3. Additional Details for the Simulations

We consider two call types and two agent groups, and an N model for call routing. The two call types are for the same type of service (related to billing), but one is in French (F) and the other in English (E). The first group (F, with 10 agents, numbered from 1 to 10) can only handle the first call type and the second group (EF, with 2 agents, numbered 11 and 12) can handle both. That is, F agents only answer calls in French and the EF agents are bilingual. Those 12 agents are the ones that worked on each day of week number 45 in our data set, and handled only those two call types. The center is open from 8h to 18h.

The arrival process for each of the two call types is piecewise-Poisson, with a gamma random arrival rate in each 15-minute time interval, and a normal copula to model the dependence between those rates. This model is explained in Oreshkin et al. (2015)¹, where it was also shown to provide a good fit to the arrival data for this HQ call center. The arrival rates were scaled down to fit our smaller number of agents. Table 7 and 8 give the rate and shape for the gamma distribution in arrival process respectively for call type F and E. Tables 9 , 10 and 11 , 12 give respectively the correlation matrix between rate for call type F and call type E.

Abandons were modeled with exponential patience times, with an abandonment rate of 1.87 call per hour for call F and an abandonment rate of 1.57 call per hour for call E. We use a routing policy that works as follows. The calls of the same type are first-come first-served. For a call type F, the router will first try to match it with an idle F agent . If there is no such free agent, then the router will try to assign it to an idle EF agent. EF agents give same priority to two calls types. If an agent of this group become free and there are calls in two waiting queues, the priority is given to call who have waited longer. The staffing vector for all 40 periods for F agents is given in Table 6. The staffing for EF agent is 2 in all periods. Calls are served in first-come-first-served order within each group.

Table 2: Observed M_k and predictions of M_k , σ^2 and v_k for some agents on Friday of week 45 for each model.

The target day that we simulate is Friday of week 45. For each selected agent, and each skill for the EF agents, we estimate the parameters of models $B1$, $B2$, $A2$, and $A3$ based on all data collected until Thursday of week 45. (We omit model $A1$ because it is dominated by $A2$ and $A3$.) Using those parameter estimates, we generate service times for each agent on that Friday. For $B1$ and $B2$, this is straightforward. For $A2$, as in equation (3.4) of the paper, we can write, omitting the specific indices for simplicity, the average of service times on the target day as $M = \beta + \gamma + \nu$ where (conditional on past information) β is a constant, γ is normally-distributed with conditional mean $\hat{\gamma}$ and conditional variance v , and ν is normal with mean 0 and variance σ_ν^2/N , where N is the number of calls of that type handled by the agent on that day. To simulate one day, we first generate γ from the appropriate normal distribution and, conditional on γ , we generate independent service times that are lognormal with mean $\beta + \gamma$ and variance σ_ν^2 . For $A3$, we proceed in a similar way. In Table 1 below,

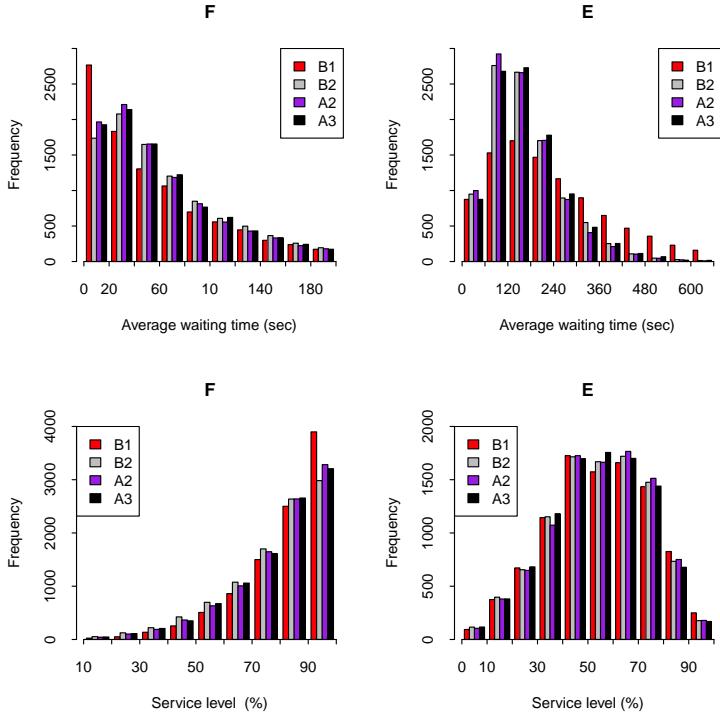

Figure 7: N model with original 12 agents.

we present the RMSE and MAPE for call types E and F, corresponding to each service-time model. And, in Table 2, we present the observed average service times for our simulated Friday, the forecasts from each service-time model, and estimated values for σ_v^2 and v for each agent and skill. Agents 11 and 12 are the EF agents considered.

In Figures 7-9, we plot histograms for the AWT simulation values corresponding to our original N model (summarized in Table 8 of the paper), our modified N model with 3 faster agents (summarized in Table 9 of the paper), and our modified N model with only 1 agent replaced with a slower one (summarized in Table 10 of the paper).

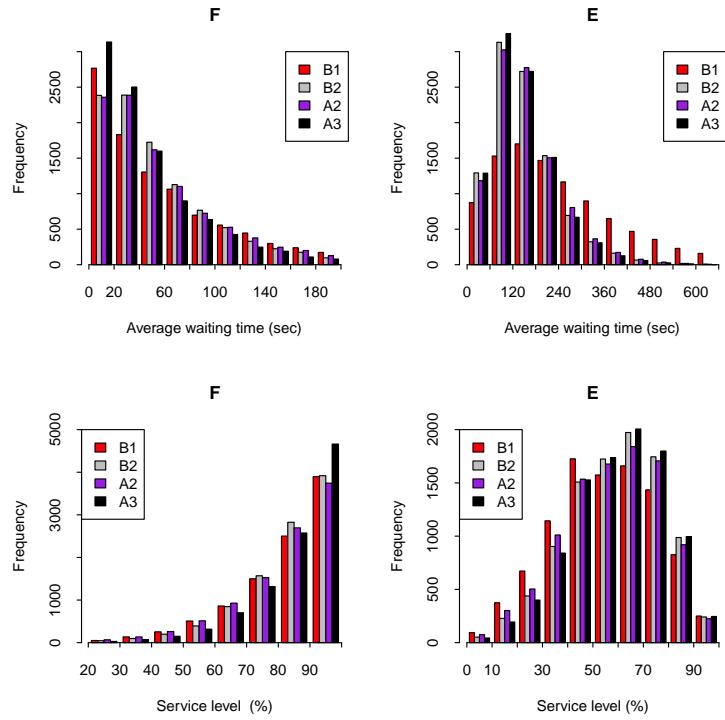

Figure 8: N model replacing 3 slow F agents with 3 fast F agents.

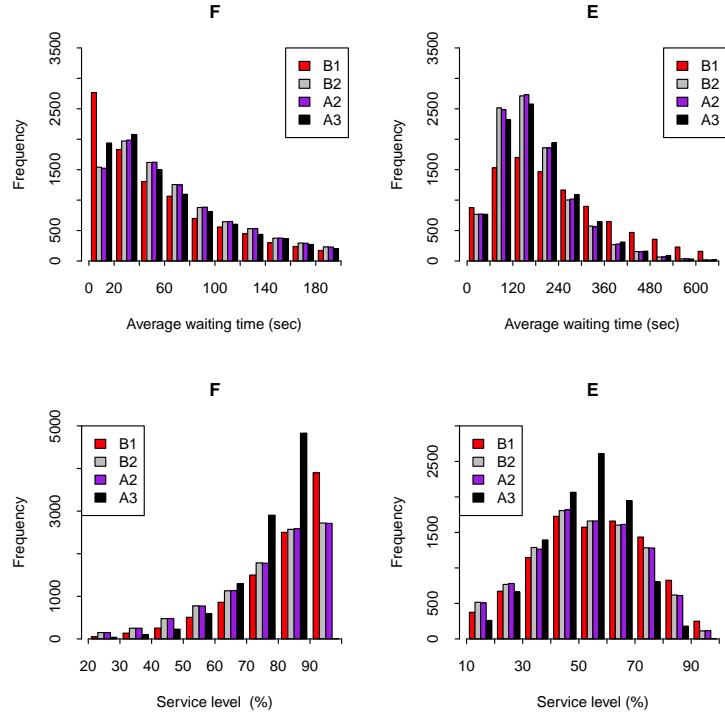

Figure 9: N model replacing one fast EF agent with one slow EF agent.
